Edited by Gregory P. Asner, Carnegie Institution for Science, Stanford, CA, and approved February 25, 2014 (received for review October 24, 2013)

Photosynthesis is the process by which plants harvest sunlight to produce sugars from carbon dioxide and water. It is the primary source of energy for all life on Earth; hence it is important to understand how this process responds to climate change and human impact. However, model-based estimates of gross primary production (GPP, output from photosynthesis) are highly uncertain, in particular over heavily managed agricultural areas. Recent advances in spectroscopy enable the space-based monitoring of sun-induced chlorophyll fluorescence (SIF) from terrestrial plants. Here we demonstrate that spaceborne SIF retrievals provide a direct measure of the GPP of cropland and grassland ecosystems. Such a strong link with crop photosynthesis is not evident for traditional remotely sensed vegetation indices, nor for more complex carbon cycle models. We use SIF observations to provide a global perspective on agricultural productivity. Our SIF-based crop GPP estimates are 50-75% higher than results from state-of-the-art carbon cycle models over, for example, the US Corn Belt and the Indo-Gangetic Plain, implying that current models severely underestimate the role of management. Our results indicate that SIF data can help us improve our global models for more accurate projections of agricultural productivity and climate impact on crop yields. Extension of our approach to other ecosystems, along with increased observational capabilities for SIF in the near future, holds the prospect of reducing uncertainties in the modeling of the current and future carbon cycle.

Significance

Global food and biofuel production and their vulnerability in a changing climate are of paramount societal importance. However, current global model predictions of crop photosynthesis are highly uncertain. Here we demonstrate that new space-based observations of chlorophyll fluorescence, an emission intrinsically linked to plant biochemistry, enable an accurate, global, and time-resolved measurement of crop photosynthesis, which is not possible from any other remote vegetation measurement. Our results show that chlorophyll fluorescence data can be used as a unique benchmark to improve our global models, thus providing more reliable projections of agricultural productivity and climate impact on crop yields. The enormous increase of the observational capabilities for fluorescence in the very near future strengthens the relevance of this study.

PNAS Early Edition | 1 of 7
resources (e.g., refs. 13, 14). The signal of the so-called spectral vegetation indices involves leaf chlorophyll content, biomass, canopy structure, and cover (15, 16), such that estimating actual productivity from vegetation indices requires additional data and modeling steps, both associated with considerable uncertainty. Complementing reflectance-based indices, global space-based estimates of sun-induced chlorophyll fluorescence (SIF) became available recently. SIF is an electromagnetic signal emitted in the 600- to 850-nm spectral window as a by-product of photosynthesis (e.g., refs. 17–19). The first global maps of SIF were derived using data from the Greenhouse Gases Observing Satellite (GOSAT) (20–23). Despite the complicated photosynthesis-SIF relationships and the convolution of the signal with canopy structure (16), SIF retrievals showed high correlations with data-driven GPP estimates at global and annual scales (21, 22), as well as intriguing patterns of seasonal drought response in Amazonia (24, 25). Recently, a global SIF data set with better spatial and temporal sampling than that from GOSAT was produced using spectra from the Global Ozone Monitoring Experiment-2 (GOME-2) instrument onboard the MetOp-A platform (26) (see SI Appendix, SIF Retrievals).

Our attention is drawn to the remarkably high SIF returns from the US Corn Belt (CB) region (Fig. 1). This highly productive area (Fig. 2D) accounts for >40% of world soybean and corn production (30). We hypothesize that the high SIF indicates very high GPP for this area and report here on studies that compare SIF retrievals to GPP models and flux tower data with the aim of gaining a unique global perspective on crop photosynthesis.

**Results and Discussion**

Looking at the spatial patterns of the maximum monthly gross carbon uptake from model results in the north temperate region (Fig. 2), we find a generally good agreement between the data-driven approach (27), that relies on data from a global network of micrometeorological tower sites (FLUXNET) (12), and the median of 10 state-of-the-art global dynamic vegetation models from the Trendy (“Trends in net land-atmosphere carbon exchange over the period 1980–2010”) project (28, 29), the former showing somewhat larger values in a small region of the US CB (Fig. 2A and B) (see SI Appendix, Model-Based GPP Data). It must be stated that the Trendy models do not include explicit crop modules, so the results from our comparisons with process-based models are intended to illustrate the potential impact of such crop-specific modules on simulations over agricultural regions. The SIF measurements, on the other hand, show large differences between the US CB and the cropland and grassland areas in Western Europe, with much enhanced SIF in the US CB (Fig. 2C). This pattern is roughly consistent with the distribution of C4 crops in the area, predominantly corn fields (Fig. 2D). Is the photosynthesis signal in the SIF retrievals disturbed by other factors, or is the US CB indeed much more productive than any area in Western Europe, which is not captured by the carbon models?

We compare year-round monthly means of flux tower-based GPP estimates at cropland and grassland sites in the United States and Europe with SIF retrievals, GPP estimates from carbon models, and spectral reflectance indices (Figs. 3 and 4 and SI Appendix, Comparison of Flux Tower-Based GPP with Model GPP, SIF and Vegetation Indices). Data-driven model GPP data are from the statistical model developed at the Max Planck Institute for Biogeochemistry (MPI-BGC) (27) (Fig. 3B) and the semiempirical moderate resolution imaging spectroradiometer (MODIS) MOD17 GPP model (31) (SI Appendix, Fig. S4). The same ensemble of 10 land surface models (28, 29) is used to evaluate the performance of process-based models (Fig. 3C). We present the comparisons in Fig. 3 without including the European cropland sites, as we want to illustrate the strong differences.
between cropland and grassland GPP over the most homogeneous ecosystems (the European cropland sites are highly fragmented, which may not be properly sampled by the 0.5° resolution at which we can grid the GOME-2 SIF retrievals; see SI Appendix, SIF Retrievals). The comparison including all types of cropland and grassland sites is provided in SI Appendix, Fig. S4.

We find that the peak monthly mean GPP derived from the flux tower data in some of the US CB sites is very high (>15 g·m⁻²·d⁻¹), whereas for the grassland sites, monthly mean GPP never exceeds 10 g·m⁻²·d⁻¹ (Fig. 3). Process-based GPP estimates compare well with the tower-based estimates over the grassland sites but show a poor correlation over the US CB (Fig. 3C). Concerning the data-driven models, there is a clear non-linear relation between flux tower and model GPP, showing that models strongly underestimate GPP at cropland sites with high fluxes. A piece-wise linear approximation reveals that deviations from the linear relation appear at GPP > 10 g·m⁻²·d⁻¹ for the MPI-BGC estimates (Fig. 3B) and at GPP > 8 g·m⁻²·d⁻¹ for the MODIS MOD17 (SI Appendix, Fig. S4). We observe that data-driven models produce similar peak GPP values for both grasslands and croplands, and that grasslands have even a higher GPP than croplands in results from the process-based models, which is not reflected by tower-based estimates. We find that SIF values exhibit a much stronger linear relationship with tower GPP at these cropland and grassland sites (Fig. 3A), and that a single linear model is able to link SIF with GPP for both croplands and grasslands. On the other hand, the good agreement between the model- and tower-based GPP estimates at grassland sites, including similar peak values, suggests that the direct comparison of flux tower data (typical footprint of <1 km²) with SIF retrievals and model data at 0.5° is acceptable for these sites.

Hence, the comparisons in Fig. 3 support the following claims: (i) SIF captures high photosynthetic signals that are observed from flux towers in the US CB, and (ii) the models underestimate crop GPP, in particular for the highly productive crop sites at the US CB. The low correlation between the crop GPP estimates by the process-based models at the US CB sites may be explained by the lack of specific crop modules in the Trendy model ensemble. Concerning the understimation of crop GPP by data-driven models, it can be argued that these cannot capture the complex dynamics required to link stable and structurally driven vegetation indices derived from remote sensing data with a highly variable physiological measure such as crop photosynthesis. On the other hand, those reflectance-based indices usually underestimate “greenness” for very dense crop canopies with high green biomass levels, such as cultivars with high fertilizer levels. This can lead to the underestimation of GPP by the data-driven models constrained by those vegetation indices.

The same flux tower-based GPP data set is compared with SIF retrievals and the enhanced vegetation index (EVI) extracted from the MODIS MOD13C2 product (15) in Fig. 4. This comparison illustrates that spectral reflectance indices, similar to the GPP models, do not scale linearly with GPP for these biome despite the good representation of the temporal patterns: The highest EVI values for grassland sites are close to the values for some of the cropland sites, whereas GPP is very different. On the other hand, it is difficult to find a global baseline value for EVI to indicate the total absence of green vegetation activity. The minimum EVI value depends on the soil nature and especially on the presence of snow (32), which can be observed in the relatively high variability of EVI in the months in which no photosynthetic activity is observed (Fig. 4 C and D). This poses a problem for the identification of start- and end-of-season times in phenological studies based on reflectance-based remote sensing data (32). The SIF observations, in turn, drop to zero following photosynthesis, which provides an unambiguous signal of photosynthetic activity.

The linear relationship between SIF data and flux tower GPP observed in Fig. 3A may be rationalized by considering that 

\[
GPP = PAR \times fPAR \times LUE_F, \quad [1]
\]

where PAR is the flux of photosynthetically active radiation received, fPAR is the fractional absorptance of that radiation, and LUE_F is the efficiency with which the absorbed PAR is used in photosynthesis (33). SIF may be similarly conceptualized as

\[
SIF(\lambda) = PAR \times fPAR \times LUE_F(\lambda) \times f_{esc}(\lambda), \quad [2]
\]

where \(\lambda\) is the spectral wavelength (~740 nm in our GOME-2 retrievals; see Materials and Methods and SI Appendix, SIF Retrievals), LUE_F is a light-use efficiency for SIF (i.e., the fraction of absorbed PAR photons that are re-emitted from the canopy as SIF photons at wavelength \(\lambda\)), and \(f_{esc}(\lambda)\) is a term accounting for the fraction of SIF photons escaping from the canopy to space. These equations can be combined making the dependence on light implicit,

\[
GPP \approx SIF(\lambda) \times \frac{LUE_F(\lambda)}{LUE_F(\lambda)} \quad [3]
\]

where we assume \(f_{esc}(\lambda) \approx 1\) because of the low absorptance of leaves in the near-infrared wavelengths at which we perform the

**Fig. 3.** Comparison of monthly mean GPP estimates at cropland flux tower sites in the US Corn Belt and grassland sites in Western Europe. Flux tower GPP estimates are compared with sun-induced fluorescence (SIF) observations at 740 nm (A) and with GPP estimates from the MPI-BGC data-driven model (B) and from process-based models (median of an ensemble of 10 dynamic global vegetation models (28, 29)) (C). Each symbol depicts a monthly average for a 0.5° grid box and those months in the 2007–2011 period for which flux tower data were available (see SI Appendix, Table S1). The P value is <0.01 in all of the comparisons. The dashed line in B and C represents the 1:1 line. Similar comparisons but including also Western Europe cropland sites are provided in SI Appendix, Fig. S4.

**Fig. 4.** Time series of flux tower-based GPP compared with SIF retrievals (A and B) and the MODIS MOD13C2 EVI (C and D) for the same cropland and grassland sites and spatiotemporal averages as in Fig. 3 (monthly averages in 0.5° grid boxes and the 2007–2011 period). SIF and EVI are plotted with the same vertical scale for cropland and grassland sites.
SIF retrievals and the relatively simple plant structure and high leaf area index of grasses and crops (34).

Empirical studies at the leaf and canopy scale indicate that the two light-use efficiency terms tend to covary under the conditions of the satellite measurement (35–37). Hence, the SIF data should provide information on both the light absorbed and the efficiency with which it is being used for photosynthesis. Vegetation indices derived from reflectance measurements from spaceborne instruments such as MODIS (15) and knowledge of the solar angle and atmospheric condition can be used to estimate PAR × fPAR (Eq. 1), but LUEP is a free parameter. These data from the CB are consistent with LUEP being much higher for intensively managed crops than for native grasslands or less managed crops.

Based on the linear relationship obtained from the comparison of SIF with tower-based GPP at all of the US and Western Europe cropland and grassland flux tower sites (GPP(SIF) = 0.10 + 3.72 × SIF; see SI Appendix, Comparison of Flux Tower-Based GPP with Model GPP, SIF and Vegetation Indices and Derivation of Spatially-Explicit Crop GPP Estimates), we have produced unique global estimates of annual crop GPP. Even though tower data outside the US CB and Western Europe were not available for the derivation of the empirical GPP–SIF relationship, we assume it to hold for all of the ecosystems in which GPP is driven by canopy chlorophyll content such as croplands and grasslands (14). We refer to this SIF-based crop GPP as the GPP predicted by ensembles of state-of-the-art data-driven (9) and process-based (28, 29) biogeochemistry models (see SI Appendix, Model-Based GPP Data). We evaluate the consistency of the different GPP estimates with the agricultural yield statistics from the National Agriculture Statistics Service of the US Department of Agriculture (USDA NASS) (38) (only North America, years 2006–2008) and the data set by Monfreda et al. (7) (global coverage, year 2000). These inventories provide large-scale cropland net primary production (NPP, biomass production by plants) estimates by combining national, state, and county-level statistics from agricultural inventories with remote sensing product and HAR data in cropland areas (see SI Appendix, NPP Data from Agricultural Inventories).

The comparison between our annual crop GPP estimates and the NPP from the USDA NASS inventory at the US CB shows that SIF-based GPP estimates are, similar to the flux tower comparisons, more linearly related to the inventory-based NPP than the model GPP (Fig. 5). Again, data-driven GPP estimates show a strongly nonlinear relationship with the inventory-based NPP, whereas the comparison with the process-based GPP estimates shows a better agreement with the SIF-based and the data-driven estimates. The same conclusions hold for the comparison of the different GPP estimates over the US CB and Western Europe with the NPP data set from Monfreda et al. (7) (see SI Appendix, NPP Data from Agricultural Inventories). Assuming that annual GPP and NPP covary linearly across the entire US CB area, this result confirms our initial statement that GPP models substantially underestimate the photosynthetic uptake of highly productive crops. However, it is challenging to relate GPP and yield-based NPP estimates in a quantitative way, as it is difficult to account for heterogeneous land cover given the coarse resolution of current SIF retrievals. For example, much of Northern Europe is a mosaic of forests (which have low SIF) and agricultural fields. This may partly explain the apparently lower productivity of European agricultural regions.

Continuing the comparison of model estimates to SIF-based crop GPP over the globe (Figs. 6 and 7 and SI Appendix, Derivation of Spatially-Explicit Crop GPP Estimates), spatial patterns of SIF-based crop GPP estimates differ from data-driven models by 40–60% in the US CB area and by 50–75% in some regions of the Indo-Gangetic Plain, the North China Plain, and the Sahel belt in Africa. Smaller differences within 0–10% are found in Europe. In terms of area-integrated annual GPP estimates (SI Appendix, Table S2), the largest differences are found in the US CB region (+43% for the data-driven models and +18% for the process-based models) and the Indo-Gangetic Plain (+55% and +39%, respectively). A remarkable difference of ~38% is also obtained between the SIF- and the process-based model estimates in the cropland areas between Brazil and Argentina. This area is often covered in biogeochemistry models as C4 grassland, which have higher productivity than the C3 grasslands. Despite the relatively important local differences, the global cropland GPP estimated from SIF is in excellent agreement with the data-driven models (17.04 ± 0.19 PgC yr−1 and 17 ± 4 PgC yr−1, respectively), whereas a difference about −12% is found with the process-based models (global cropland GPP of 20 ± 9 PgC yr−1). These annual GPP numbers must be compared with the 14.8 PgC yr−1 given by Beer et al. (9) for croplands, and 123 PgC yr−1 for the total of all biomes. Time series of SIF- and model-based crop GPP over some selected agricultural regions gives insight into the differences observed in the annual GPP estimates (Fig. 7). The variation range of the monthly GPP estimates from SIF observations agrees well with the estimates from data-driven models in all of the selected cropland regions, which supports the consistency of our approach of scaling SIF to GPP using direct comparisons between GOME-2 SIF data and flux tower-based GPP. Also, the seasonal variations of data-driven and SIF-based GPP estimates are in general very consistent in all regions, and especially in Western Europe and China (Fig. 7 B–D). Estimates over the US CB and the Indo-Gangetic Plain also show the same phenological trends, but the SIF-based GPP estimates over the US CB are systematically higher than data-driven estimates by about 20% throughout the year (Fig. 7 A). Over India, both GPP estimates coincide for the so-called ‘Rabi’ crops sown in winter and harvested in the spring, but SIF-based GPP is about 40% higher than data-driven GPP for the ‘Kharif’ or monsoon crops sown around June and harvested in autumn (Fig. 7 C). This large difference in the estimated crop GPP over India in autumn explains the time shift of the global SIF-based crop GPP with respect to the data-driven models (Fig. 7 F). On the other hand, the tested process-based models from the Trendy ensemble compare very well with data-driven models and SIF over the Western Europe region despite the lack of crop-specific modules in the Trendy models. We hypothesize that this is due to the fact that West European crops mostly follow the seasonality of grasslands, by which crops are often represented in the models. However, these models fail to describe crop phenology at the other regions and, more significantly, the multiple cropping in China and India. A time shift of the peak GPP estimates at the US CB with respect to SIF-based and data-driven GPP can be explained by the differing uncertainties associated to irrigation and also by the fact that sowing and harvesting time in the US CB is different from the lifetime of natural grassland (peak in June), as opposed to Western Europe. Also, process-based models substantially underestimate the peak GPP values for the US CB, India, and China regions, and tend to overestimate GPP in South America, which explains the
crop GPP is derived through the scaling of SIF retrievals with the relationship \( GPP(SIF) \) and the output of data-driven models (C and E) and process-based models (D and F). Spatially explicit GPP is derived through the scaling of SIF retrievals with the relationship \( GPP(SIF) = -0.10 + 3.72 \times SIF \) (see SI Appendix, Derivation of Spatially-Explicit Crop GPP Estimates). Cropland GPP is given in per-total-area units. The absolute difference \( \Delta GPP \) is calculated as \( GPP(SIF) - GPP(model) \), and the relative difference is calculated as \( \Delta GPP \) over \( GPP(model) \).

Spatial patterns observed in the annual GPP comparisons in Fig. 6. These results illustrate the need for specific crop modules in global dynamic vegetation models.

Considering the growing pressure on agricultural systems to provide for an increasing food and biofuel demand in the world, a global, time-resolved, and accurate analysis of crop productivity is critically required. Crop-specific models or improved process-based biogeochemistry models including explicit crop modules could provide projections of agricultural productivity and climate impact on crop yields (e.g., refs. 39–41). However, local information such as meteorology, planting dates and cultivar choices, irrigation, and fertilizer application are needed. In this

However, local information such as meteorology, planting dates and cultivar choices, irrigation, and fertilizer application are needed. In this
work, we have demonstrated that spaceborne SIF retrievals can provide realistic estimates of photosynthetic uptake rates over the largest crop belts worldwide without need of any additional information. This finding indicates that SIF data can help us improve our current models of the global carbon cycle, which we have shown to substantially underestimate GPP in some large agricultural regions such as the US CB and the Indo-Gangetic Plain. The launch of the Orbiting Carbon Observatory-2 and the Sentinel 5-Preursor satellite missions in 2014 or 2015 will enormously improve the observational potential for SIF, up to a 100-fold increase in spatiotemporal resolution (42, 43). This will especially benefit measurements over the typically fragmented agricultural areas, which suggests that SIF-based estimates of crop photosynthesis will soon become a unique data set for both top-down and bottom-up modeling of agricultural productivity and the benchmarking of carbon cycle models.

Materials and Methods

We have used monthly averages of SIF retrievals (26) from the GOME-2 instrument onboard the MetOp-A platform to produce unique estimates of global crop GPP. GOME-2 SIF retrievals are performed in the 715- to 758-nm spectral window. Single retrievals are quality-filtered and aggregated in a 0.5° grid. The GOME-2 SIF data set used in this study covers the 2003–2010 time period (see SI Appendix, Model-Based GPP Data). Ensembles of process-based and data-driven biogeochemistry models have been analyzed to assess the ability of global models to represent crop GPP (see SI Appendix, Model-Based GPP Data). The process-based model ensemble comprises the 10 global dynamic vegetation models (CLM4C, CLM4CN, HYLAND, LPJ, LPJ-GUESS, ORCHIDEE, SDGVM, TRIFFID, and VEGAS) included in the Trends in net land carbon exchange over the period 1980–2010 (Trendy) project (28, 29). It must be noted that these models do not include explicit crop modules. The data-driven model ensemble consists of the MTE1, MTE2, ANN, KGB, and LUE models used by Beer et al. (9). In addition, monthly GPP estimates from the MPI-BGC data-driven model (27), which corresponds to the MTE1 in the data-driven model ensemble, and the MODIS GPP product (MOD17) (31) have been compared with monthly flux tower-based GPP over croplands and grasslands to evaluate the ability of data-driven models to reproduce GPP at those sites. Cropland GPP is calculated from the SIF observations and the model ensembles as the product of the total GPP in each 0.5° grid box by the fraction of cropland area given by Ramankutty et al. (6) (see SI Appendix, Derivation of Spatially-Explicit Crop GPP Estimates). EVI data in Fig. 4 and SI Appendix, Comparison of Flux Tower-Based GPP with Model GPP, SIF and Vegetation Indices, have been extracted from the MODIS MOD13C2 product (15).

23. Joiner J, et al. (2012) Filling-in of near-infrared solar lines by terrestrial fluorescence from GOSAT: Patterns of plant fluorescence with gross primary productivity and/or advice on their use, Eumetsat for the GOME-2 data, the Trendy project for the process-based model runs, and the USDA NASS for their agricultural inventory data. We also thank the two anonymous reviewers and Dr. Asner for their valuable suggestions and comments. MODIS MOD17 GPP data were downloaded from the server of the Numerical Terradynamic Simulation Group at the University of Montana, MODIS MOD13 data were obtained from the MODIS Land Processes Distributed Active Archive Center, and MERIS-MTIC from the Inforterra Ltd server. This work used eddy covariance data acquired from AmeriFlux and GHG-Europe. 1 SIF retrievals

We use SIF data derived from spectral radiance measurements by the GOME-2 instrument onboard the Eumetsat’s MetOp-A platform launched in October 2006. Details can be found in [1]. GOME-2 measures in the 240–790 nm spectral range with relatively high spectral resolution (∼0.2–0.4 nm), signal-to-noise ratio (∼1000–2000), and a footprint size of 40×80 km². SIF retrievals are performed in the 715–758 nm spectral window overlapping the second peak of the SIF emission. The retrieval method disentangles SIF from the spectral signals of atmospheric absorption and scattering and of surface reflectance which affect the measured top-of-atmosphere radiance. The retrievals are quality-filtered and binned in a 0.5° lat-lon grid. GOME-2 data between 2007 and 2011 have been used in this work.

Fig. S1 presents SIF retrievals from GOME-2 and GOSAT’s Fourier Transform Spectrometer (FTS) data over the northern temperate region. NDVI from the MODIS MOD13C2 product is also shown for reference. The retrieval approach applied to the GOSAT data is described in Guanter et al. [2]. The retrieval of SIF from GOSAT data is much simpler than that for GOME-2 thanks to the very high spectral resolution of the GOSAT’s FTS (∼0.025 nm), which allows to use narrow fitting windows (hence simpler modeling of the background surface reflectance) and to resolve individual solar Fraunhofer lines (i.e. free from contamination by atmospheric absorption, mostly O₂ in this spectral range). GOSAT/FTS measurements consist of round field-of-views of about 10 km diameter separated by hundreds of kilometers. The random component of the single-retrieval error is high, in the range of 50–100%, due to the narrow fitting window used for the retrieval and the relatively low signal-to-noise ratio (∼100–300) of the FTS. Global composites of monthly SIF from GOSAT retrievals are typically produced by averaging in 2° gridboxes. Despite the noise and the low spatial resolution of the GOSAT SIF composites, we consider them to be highly accurate (free from systematic errors) due to the simplicity of the retrieval approach based on narrow fitting windows and solely Fraunhofer lines. Therefore,
Fig. S 1: Monthly composites (July 2009) of SIF retrievals from GOSAT/FTS and MetOp-A/GOME-2 measurements. NDVI from the MODIS MOD13C2 product is also shown for reference. GOME-2 retrievals are for a spectral fitting window centered around 740 nm (715–758 nm) and are gridded in 0.5° cells, whereas GOSAT retrievals are for a narrow window at 757 nm and are gridded in 2° cells.

The good comparison between the spatial patterns in the GOSAT and the GOME-2 SIF supports the consistency of the GOME-2 SIF data used in this work, and in particular of the outstanding SIF levels observed at the Midwest US in the GOME-2 data (Fig. 1–2 of the main text). Slight differences in the spatial patterns of GOSAT and GOME-2 SIF can be explained by the lower precision of the GOSAT retrievals, which leads to noisier SIF composites, and the different overpass times (morning for MetOp-A, noon for GOSAT) which makes the latitudinal differences in the solar flux received in the north and the south to be greater for GOSAT than for GOME-2. The absolute SIF values differ for GOME-2 and GOSAT-FTS because of the different retrieval wavelengths and instantaneous illumination fluxes associated to the overpass time of each satellite.

2 Model-based GPP data

We have used global GPP estimates from ensembles of data-driven and process-based models as follows:
• **Data-driven models** are based on the calculation of GPP with empirical and semi-empirical relationships between GPP and a series of diagnostic variables (e.g. vegetation parameters such as the fraction of absorbed photosynthetically active radiation and meteorological variables such as short-wave radiation or vapor pressure deficit). As representative of state-of-the-art data-driven methods, we have used annual GPP estimates from 5 of the data-driven models described in Beer et al. [3], namely MTE1, MTE2, ANN, KGB and LUE. These models differ with each other in how the relationship between the diagnostic variables and GPP is expressed.

In addition, monthly GPP estimates from the MTE1 model, referred to as Max Planck Institute for Biogeochemistry (MPI-BGC) model [4] in the main text, and from the MODIS GPP model (MOD17) [5] are used in the comparison with flux tower GPP in Fig. 2 of the main text and Fig. S4, respectively. The MPI-BGC GPP data set is produced through the global upscaling of site measurements of carbon dioxide fluxes. This is based on a Model Tree Ensemble approach for a statistical formulation of the relationship between GPP and vegetation parameters derived from remote sensing data and meteorological variables from re-analysis products. MOD17 GPP is derived from a production-efficiency approach consisting in the formulation of GPP as the product of absorbed photosynthetically-active radiation derived from satellite and meteorological data and tabulated light use efficiency.

• **Process-based models** or dynamic global vegetation models (DGVMs), are based on mathematical representations of physiological and ecological mechanisms driving productivity among other vegetation responses. The DGVMs in our ensemble of process-based models are part of the Trendy activity\(^1\) intended to intercompare *Trends in net land - atmosphere carbon exchange* over the period 1980–2010. We have use the CLM4C, CLM4CN, HYLAND, LPJ, LPJ-GUESS, OCN, Orchidee, SDGVM, TRIFFID, and VEGAS models. Model outputs were available at different spatial resolutions. The data from the LPJ, LPJ-GUESS, Orchidee and VEGAS models were simulated at 0.5°×0.5° resolution, CLM4C and CLM4CN at 2.5°×1.875°, and OCN, TRIFFID and HYLAND other at 3.75°×2.5°. All 10 models have been resampled to the 0.5° grid used for the SIF measurements, the data-driven model ensemble and the NPP inventories.

Fig. S2 shows the median and the standard deviation of the annual GPP from the 5 data-driven models from Beer et al. [3] and the 10 process-based Trendy models from Piao et al. [6], Sitch et al. [7] that we have used in this study. The median of the annual GPP from the two model ensembles shows similar absolute values, although there are some spatial differences, especially in North America. The spread of GPP estimates is significantly smaller for the data-driven models than for the process-based models.

\(^1\)http://dgvm.ceh.ac.uk/node/9
Fig. S 2: Median (top row) and mean absolute deviation (bottom row) of annual GPP estimates in North America and Western Europe from the data-driven and process-based model ensembles used in this work. Details about each model ensemble can be found in Beer et al. [3] and Piao et al. [6], Sitch et al. [7], respectively.

3 Comparison of flux tower-based GPP with model GPP, SIF and vegetation indices

We used fourteen eddy flux sites from the FLUXNET network [8] (Table S1). Six of these sites are located in crop fields in the US Corn Belt. The remaining eight stations include five crop sites and three grassland sites located across Europe. Sites have been selected on the basis of landscape homogeneity in the GOME-2 grid and on data availability in the period of interest (2007–2011). To determine landscape homogeneity, we used land cover type data from the MODIS Collection 5 MCD12C1 product (Friedl et al. [9]) and EVI data from the MODIS MOD13C2 product (Huete et al. [10]), both with spatial resolution of 0.05°. For a site to be selected for the study, the dominant vegetation cover type at the flux site (either cropland or grassland) must represent more than 60% of the GOME-2 pixel area, and the standard deviation of the EVI must be less than 0.10 (see Table S1). We used the Level 4 data product for the six US crop sites from the AmeriFlux website\(^2\), and from the GHG-Europe database\(^3\) for the eight Europe sites. Monthly GPP values were used in our investigation. GPP is estimated by partitioning the observed net flux into GPP and ecosystem respiration as discussed in Reichstein et al. [11] and Papale et al. [12].

For each site, SIF was extracted based on the coordinates of the flux tower, and averaged to monthly means when at least 5 SIF retrievals were available. Three US crop sites (US-IB1, Ne2-3, Ro1) are very close to big cities. To avoid signal contamination from urban areas, we extracted SIF from a nearby pixel fulfilling the homogeneity criteria. Given that flux measurements are usually representative of a large area in homogeneous landscapes (i.e., US-IB1 is representative of central Illinois), we assumed that SIF (or EVI and NDVI) from nearby grid boxes can represent the footprint of the flux towers. Monthly SIF

\(^2\)http://ameriflux.ornl.gov/
\(^3\)http://www.europe-fluxdata.eu/
and GPP were averaged over the 2007–2011 observation period for each month to minimize uncertainties due to the different spatial scales of the SIF retrievals and the flux tower data. This uncertainties occur because both corn and soybean fields exist in the GOME-2 footprint for the US flux sites. A mixed signal of corn and soybean is therefore sampled by the GOME-2 footprint, while the eddy covariance tower measured flux either from corn or soybean for each year. Multi-year averaging may help reduce this mismatch.
Table S1: Details of the flux tower sites used in this study. LC stands for Land Cover class, max(LC) stands for the percent of dominant vegetation cover within the GOME-2 pixel, EVI is the MODIS Enhanced Vegetation Index, and $\sigma$(EVI) represents the standard deviation of EVI within the GOME-2 pixel.

</table>
Reflectance-based vegetation indices derived from satellite observations [e.g. 10, 25] provide information about vegetation *greenness* (i.e. a combination of biomass, chlorophyll content and structural effects) and have also been reported to be good indicators of gross primary production [e.g. 26]. The data-driven GPP models combine these reflectance-based proxies for green biomass and canopy light interception with meteorological inputs modulating photosynthesis at the ecosystem scale.

To complete the comparison of model GPP with fluorescence and tower-based GPP discussed in the main text, we have also analyzed the relationship between flux tower GPP and the normalized difference vegetation index (NDVI) [27], the enhanced vegetation index (EVI) [10], both extracted from the MOD13C2 product, and the MERIS terrestrial chlorophyll index (MTCI) [28]. The NDVI is the most widely used vegetation index in the last decades. The EVI is a modification of the NDVI intended to improve the response of the NDVI for high green biomass levels and to reduce the sensitivity to atmospheric effects. The MTCI is designed to provide a high sensitivity to chlorophyll content through the sampling of the so-called red-edge window between the red and the near-infrared spectral regions.

Fig. S3 displays maps of the EVI, NDVI and MTCI for July 2009 and the same area as the GPP and SIF maps shown in Fig. 2 of the main text (please, note that maximum monthly values instead of July values are plotted in Fig. 2 of the main text, so this comparison is only approximate). The data-driven GPP from the MODIS MOD17 product is also shown. The NDVI appears to be close to saturation in the most densely vegetated areas of North America and Europe. This is not happening for the EVI, which shows a somewhat higher signal in the midwest and the east coast of the US than in Europe, in line with the spatial patterns of SIF and GPP MPI-BGC (Fig. 2 of the main text). No significant differences between Europe and the US are observed in the MOD17 GPP data. On the other hand, the spatial patterns of the MTCI at the US Corn Belt are the most similar ones to those of SIF. This could be due to the fact that both SIF and the MTCI are most sensitive to canopy chlorophyll content for the high levels of leaf-area index found at the peak of the growing season for the corn and soybean crops in the US Corn Belt.

The same three indices have been compared with flux tower-based GPP estimates as we have done with MPI-BGC GPP, process-based GPP from the Trendy models and SIF in Fig. 3 of the main text. Results are shown in Fig. S4, in this case also including the European crop sites not included in Fig. 3 of the main text. Points to be noted are (i) the relatively bad comparison between GPP and both EVI and NDVI for the US crops, (ii) the good correlation between EVI and GPP when the comparison is performed for all three biomes, (iii) the lower values of EVI and MTCI at the grasslands sites, which agrees with SIF and the tower-based GPP, but not with the data-driven GPP estimates, and (iv) the good performance of the MTCI to track GPP in the US crops. These results, together with the conclusions extracted from Fig. 3 of the main text, support our approach of selecting SIF as the best input to upscale cropland GPP from the tower footprint to the regional scale. The relationship $GPP(SIF) = -0.10 + 3.72 \times SIF$ is used for this upscaling.
Fig. S 3: Maps of GPP from the MODIS MOD17 product, NDVI and EVI from the MODIS MOD13C2 product and the MERIS MTCI for July 2009 and the same region of the GPP and fluorescence maps displayed in Fig. 2 of the main text. Please, note that maximum monthly values instead of July values are plotted in Fig. 2 of the main text, so the comparison is only approximate.
Fig. S 4: Similar to Fig. 3 of the main text but including the European cropland sites. Tower-based GPP is compared with SIF, GPP MPI-BGC and GPP MOD17 (top) and with EVI, NDVI and MTCI data (bottom).
4 Derivation of spatially-explicit crop GPP estimates

The monthly composites of SIF at 0.5° are scaled to GPP with the linear relationship derived from the comparison of SIF with flux tower-based GPP shown in Fig. S4a (GPP(SIF) = -0.10 + 3.72 × SIF). Model-based GPP maps are generated as the median GPP per grid cell from the data-driven and process-based model ensembles described before. We have estimated crop GPP from the total GPP in the grid box by multiplying the total GPP by the fraction of cropland area in the gridbox described in Ramankutty et al. [29] and downloadable from http://www.geog.mcgill.ca/~nramankutty/Datasets/Datasets.html. As a result, we obtain the cropland GPP per unit total area, as shown in Fig. 6a of the main text. Comparison of annual, area-integrated crop GPP estimated from SIF and the data-driven and process-based models are provided in Table S2.

Table S 2: Annual, area-integrated GPP estimates over the US Corn Belt (35–50°N, -105–80°E), Western Europe (35–55°N, -10–25°E), India (23–33°N, 70–90°E), China (30–49°N, 110–135°E), South America (-40–-20°N, -45–-70°E), and the globe from the median of the data-driven and process-based biogeochemistry model ensembles and the scaled SIF. These regions match those used to produce Fig. 7 of the main text. Relative ∆GPP is calculated as SIF-based GPP minus model GPP over model GPP. Uncertainties are derived from the standard deviation of the ensembles in the case of the GPP models and from the errors in the slope and intercept in the linear regression in Fig. S4a for the scaled SIF.

5 NPP data from agricultural inventories

The SIF- and model-based crop GPP estimates have been compared with crop net primary productivity (NPP) estimates derived from agricultural inventories to produce Fig. 5 of the main text. Large-scale NPP estimates have been provided by the agricultural inventory data sets described in USDA-NASS [30] and Monfreda et al. [31]. The USDA NPP inventory was estimated using a statistical method that includes factors for dry weight, harvest indices, and root:shoot ratios multiplied by yield data from the National Agricultural Statistics Service (NASS). This method has been documented and published by Hicke and Lobell [32], Hicke et al. [33], Prince et al. [34]. U.S. county-level estimates of croplands production (P, in units of MgCy⁻¹) dataset is available in http://cdiac.ornl.gov/carbonmanagement/cropcarbon/. Data from the three most recent years (2006–2008) was used for
Fig. S 5: Crop NPP per harvested area in North America from the global inventory by Monfreda et al. for 2000 (a) and the USDA inventory (2006 and 2008) [33].

comparison. To derive the spatial distribution of cropland GPP, county-level NPP (kgCm$^{-2}$y$^{-1}$) was collocated in ArcGIS to a layer of the cultivated area of the US during 2008–2012. To compute NPP, we divide P by the total crop area of each county. The cultivated layer data is available from USDA NASS database at http://www.nass.usda.gov/research/Cropland/Release/index.htm. Regarding the global inventory by Monfreda et al., it is based on the aggregation of 175 crop classes in a 5 min by 5 min grid following a method similar to the one proposed by Prince et al. [34] for the US. Monfreda et al. data corresponds to the year 2000.

Both USDA-NASS and Monfreda et al. NPP data sets are derived from the crop yields, and have units of per-harvested-areas (Fig. S5). NPP is converted from per-harvested-area to per-total-area units through the multiplication by the fraction of harvested area as described in Monfreda et al. (Fig. S6). The fraction of harvested area is calculated by summing the fraction of harvested area for each of the 175 crop classes considered by Monfreda et al. (data available from http://www.geog.mcgill.ca/~nramankutty/Datasets/Datasets.html).

The comparison of NPP from the USDA inventory with GPP from the SIF retrievals and the data-driven and process-based models for the US Western Corn Belt is shown in Fig. 5 of the main text. The same comparison for the NPP from Monfreda et al. for both the US and Western Europe is displayed in Fig S7.
Fig. S 6: Cropland area and net primary production data sets from Ramankutty et al. [29] and Monfreda et al. [31] The fraction of cropland area expresses the ratio of cropland to total area in each 0.5° grid cell. The harvest ratio is the ratio of harvested-to-cropland area. The fraction of harvested area has been calculated from single fractions of harvested area provided by Monfreda et al. [31] for a total of 175 crop classes. The NPP per total area is calculated as the product of the original per-harvested-area NPP data from Monfreda et al. by the fraction of harvested area.
Fig. S 7: Same as Fig. 5 of the main text but for the NPP data set from the agricultural inventory by Monfreda et al. and showing results also for the Western Europe area (40–55°N, -5–15°E).
